Foreword

This edition of the Container Port Performance Index (CPPI) marks the sixth consecutive year of publication. Over this period, the CPPI has matured into a proven and widely used dataset, providing a consistent, data-driven assessment of container port performance worldwide. Its continued relevance reflects both the robustness of its methodology and the growing recognition of ports as critical enablers of trade, competitiveness, and economic development.

This year's edition is particularly timely. Global supply chains remain exposed to repeated shocks, including geopolitical tensions, climate-related disruptions, and continued volatility in shipping networks. In this context, the time vessels spend in port has become even more central to the functioning and resilience of international trade. Efficient ports are not only a source of competitiveness but also a key determinant of how well supply chains absorb and recover from disruptions.

The CPPI was established to measure container port performance, focusing on vessel time in port as an objective and comparable indicator. Since the index's inception, a series of global disruptions has revealed an additional, important insight: port performance and supply chain stress are closely interconnected. Supply chain stress affects port operations through schedule unreliability, vessel bunching, and congestion, while prolonged time in port feeds back into broader supply chain stress by tying up vessel capacity and propagating delays. As such, the CPPI has also proven to be a useful lens for observing and assessing supply chain stress.

Against this background, this year's report focuses explicitly on the mutual relationship between vessel time in port and supply chain stress, both globally and at the individual port level. By examining how changes in port performance align with broader measures of disruption, the report highlights the two-way dynamics between ports and the supply chains they serve.

With each additional year of data, the CPPI becomes more valuable. The growing time series allows stakeholders to move beyond single-year rankings to monitor trends, identify structural strengths and weaknesses, and assess how ports respond to shocks over time. The Annex, available for download, contains the full CPPI dataset for all six years, along with key reference information, including regional and income-group averages, the share of vessel time spent at berth, and sample sizes. This allows users to benchmark ports against any subset of other ports and conduct their own analysis of trends, enhancing the usefulness of the CPPI as a benchmarking and diagnostic tool for policymakers, port authorities, operators, and development partners.

The World Bank Group stands ready to support its clients in improving port performance as part of broader efforts to strengthen trade facilitation, connectivity, and logistics. Through policy dialogue, analytical work, and investment financing from the World Bank and the International Finance Corporation, the World Bank Group supports reforms and investments across the port and maritime sector, helping countries enhance efficiency, resilience, and sustainability.

S&P Global Market Intelligence, through its maritime and port analytics, continues to provide the high-quality underlying data and analytical depth that underpin the CPPI. Beyond the index itself, S&P Global stands ready to support clients with more granular analysis, tailored benchmarks, and data-driven insights into port operations and global shipping networks.

Together, we hope that this sixth edition of the CPPI will continue to inform evidence-based dialogue, support better decision-making, and contribute to stronger, more resilient global supply chains.

Head of Maritime & JOC

Acknowledgements

This report was prepared jointly by the Transport and Logistics Global Practice of the Infrastructure Vice-Presidency at the World Bank and the Global Insight Division of S&P Global Market Intelligence.

The World Bank team for this report was led by Jan Hoffmann (World Bank Global Lead for Maritime Transport and Ports), under the guidance of Nicolas Peltier-Thiberge (World Bank Acting Manager, Knowledge Bank Infrastructure Transport Policy and Regulation) and Bertrand De la Borde (World Bank Group Director, Transport and Logistics). The team comprised Simona Sulikova, Dominik Englert, Rico Salgmann, Dominique Guillot, Sophia Parker, Isabelle Rojon, and Maximilian Weidenhammer.

The S&P Global Market Intelligence team was led by Turloch Mooney (Head of Port Intelligence & Analytics), under the guidance of Guy Sear (Vice-President and Head of Maritime & JOC). The team comprised Michelle Wong, Dan Clemensen, and Shazleen Wan.

The team would like to extend special thanks to the following experts for their comments on the draft of the report: Andre S Van Hoeck, Christina Wiederer, Daria Ulybina, Pierre A. Pozzo di Borgo, and Stephane Straub.

Abbreviations

AIS	Automatic Identification System
CI	Crane Intensity
COVID-19	Coronavirus Disease 2019

UN/LOCODE	United Nations Code for Trade and Transport Locations

Glossary

All fast: The point when the vessel is fully secured at berth and all mooring lines are fast.

Arrival time/hours: The total elapsed time between the vessel's AIS-recorded arrival at the actual port limit or anchorage (whichever is earlier) and all lines fast at the berth.

Berth hours: The time between all lines fast and all lines released.

Berth idle: The time spent on berth without ongoing cargo operations. Includes time between all fast to first move and last move to all lines released.

Call size: The number of container moves per port call, inclusive of discharge, load, and restowage.

Cargo operations: The time between first and last container moves during which cargo is actively exchanged.

Crane intensity (CI): The quantity of cranes deployed to a ship's berth call, calculated as total gross crane hours divided by operating hours.

Factor analysis (FA): A statistical method used to describe variability among observed, correlated variables in terms of fewer unobserved variables called factors.

Finish: Total elapsed time between the last container move and all lines released.

Global Supply Chain Stress Index (GSCSI): An index compiled by the World Bank measuring global logistics and shipping disruptions, including congestion.

Gross crane hours: Total working time for all cranes deployed for a vessel call without deductions.

Gross crane productivity: Call size or total moves divided by total gross crane hours.

Hub port: A port used by deep-sea mainline ships as a transshipment point for smaller feeder ports in its region.

Moves: Total container moves: discharge + restowage + load. Excludes hatch covers and non-container work.

Moves per crane: Total moves for a call divided by the crane intensity.

Port call: A call to a container port by a container vessel in which at least one container is discharged or loaded.

Port hours: The number of hours a ship spends at/in port, from arrival at port limits to sailing from the berth.

Port limits: The anchorage zone or location of pilot embarkation/disembarkation, whichever is earliest.

Port to berth hours: The time from port limits or anchorage to the moment the vessel is all fast alongside the berth.

Ship size: Nominal capacity in twenty-foot equivalent units (TEU).

Start: The time elapsed from berthing (all lines fast) to first container move.

Steam-in time: The time required to steam-in from the port limits to berth all fast.

Transshipment: Containers transferred between ocean-going container ships or from mainline to feeder vessels.

Time in port: For CPPI calculations, this includes the time between arrival at anchorage or pilot station and departure from berth. The time in port between departure from berth and exit from port limits is not included in the CPPI calculations.

Waiting time: Total time from when a vessel enters anchorage until it departs, excluding movement under 0.5 knots for at least 15 minutes.

Executive Summary

Executive Summary

The Container Port Performance Index provides a consistent, data-driven assessment of container port performance based on observed vessel time in port. Now in its sixth year of publication, the index has evolved into a mature global benchmark that allows comparison across ports, regions, and income groups, and over time. It was developed in response to the need for an objective performance measure that reflects how ports function within real maritime networks, rather than relying on self-reported metrics or partial operational indicators. By focusing on vessel time in port, the index captures the combined effect of nautical access, berth availability, cargo handling productivity, yard operations, coordination among stakeholders, and hinterland interfaces.

The index's relevance has increased as global supply chains have become more exposed to shocks. Over the period covered by the CPPI, container shipping and port systems have faced unprecedented disruptions, including the COVID-19 pandemic, sharp swings in demand, congestion cascades, and, more recently, geopolitical rerouting and climate-related events. These developments have highlighted the central role of ports in the functioning of global trade systems. Ports influence not only local efficiency outcomes but also the reliability, cost, and resilience of international supply chains. The growing CPPI time series allows stakeholders to move beyond one-year rankings toward trend analysis, enabling a better understanding of structural performance, cyclical volatility, and recovery capacity.

The CPPI is both a benchmark and a diagnostic tool. It allows policymakers, port authorities, operators, and development partners to observe how port performance evolves, responds to external shocks, and compares with peer groups. At the same time, the index has increasingly proven useful as a lens for observing broader supply chain stress, given the tight relationship between vessel time in port and congestion, schedule reliability, and effective shipping capacity.

Section 1: Trends in Vessel Time in Ports in 2025

In 2025, the global average CPPI shows a slight deterioration relative to the 2024 benchmark, indicating longer vessel time in port on average. This overall movement reflects a combination of regional patterns. The aggregate result is not driven by a uniform global shift, but by offsetting developments across regions and individual ports, with external shocks and structural factors shaping outcomes differently across locations.

Vessel time in port in 2025 continued to show clear regional and income-related differences. Ports in upper-middle-income and high-income economies maintained shorter turnaround times on average, supported by stronger infrastructure, higher crane intensity, more advanced digital systems, and better coordination among stakeholders. Several ports in upper-middle-income countries, particularly in East and South Asia, again outperformed many high-income peers, reflecting export orientation, inter-port competition, and sustained investment momentum. Ports in Europe and North America continued their recovery from earlier disruption but some remained affected by congestion, labor constraints, and hinterland bottlenecks. Ports in Sub-Saharan Africa generally recorded longer vessel times in port, often linked to import-dominated trade structures, capacity constraints, and limited competition. The Middle East experienced a deterioration in performance following schedule disruptions associated with the Red Sea crisis, illustrating the vulnerability of even well-equipped ports to geopolitical shocks.

Top performers and improvers. At the global level, the top five performers in 2025 were Fuzhou, Dalian, Salalah, Mawan, and Chiwan, all characterized by consistently short vessel turnaround times. The leading improvers between 2020 and 2025 were Port Elizabeth, Khalifa Bin Salman Port, Posorja, Göteborg, and Muhammad Bin Qasim. The top improvers in 2025 compared to 2024 are Durban, Freeport, Coega (Ngqura) Port, Cristobal, and Manzanillo (Mexico). These ports represent a range of regions and starting conditions, indicating that improvement is achievable through different pathways, including capacity expansion and operational improvements.

Lessons learned. Several broad lessons emerge from the performance patterns observed among the highest-ranked ports and the strongest improvers over the CPPI period. These lessons are structural and operational rather than specific to individual locations.

First, high performance is associated with the ability to minimize time absorption. Time absorption refers to the extent to which vessels spend additional time in port beyond the baseline operational requirement, reflecting queuing, waiting, and idle berth time, as well as the port's ability to cope with volatile arrival patterns and recover from disruption. Top-performing ports are characterized by short, predictable vessel turnaround times for a given workload. They combine adequate nautical access, sufficient berth and crane capacity, and well-integrated yard operations with stable coordination routines. Importantly, they limit unproductive waiting time and maintain a high share of vessel time in productive berth operations.

Second, resilience matters as much as peak efficiency. Ports that perform consistently well are not those that optimize for maximum throughput under ideal conditions, but those that maintain operational discipline under volatility. This capacity to recover quickly has become increasingly important in an environment where shocks are frequent and often external.

Third, effective coordination and governance help improve performance and resilience. Ports that perform well, or improve rapidly, tend to operate in environments where roles and incentives among public authorities, terminal operators, and service providers are aligned. Predictable regulatory frameworks, transparent concession arrangements, and effective data sharing reduce friction and allow ports to respond more flexibly to shocks.

Fourth, digitalization supports both efficiency and resilience. The ability to share reliable, timely information on vessel arrivals, berth status, yard conditions, and landside flows improves predictability and reduces the amplification of shocks. Digital tools that improve planning and sequencing help ports shift from reactive to anticipatory operations, which is critical in managing volatile arrival patterns.

Section 2: Container Port Performance and Supply Chains

The analytical focus of this edition is the mutual relationship between container port performance and supply chain stress. The CPPI time series from 2020 to 2025 demonstrates a strong co-movement between vessel time in port and a range of global and regional stress indicators. Periods of high supply chain stress are consistently associated with longer vessel turnaround times and lower CPPI scores, while periods of easing stress coincide with improved port performance. Importantly, causality runs in both directions.

Supply chain stress has a measurable, negative impact on port performance. When schedules become unreliable, and demand volatility increases, vessels arrive at ports out of sequence and often in clusters. This reduces terminals' ability to plan berth allocation, labor deployment, and yard operations. Even ports with high baseline capability experience longer turnaround times when arrival patterns become irregular. The result is longer waiting times at anchor and berth, which lowers measured performance.

The CPPI includes non-productive time spent waiting or at anchor in port during periods of disruption. This dynamic has been particularly visible during recent global shocks. During periods of intense disruption, a large share of the container fleet has been delayed, with vessels arriving days behind schedule. Such delays compress arrival patterns, producing short but intense congestion episodes that overwhelm available capacity. These burst congestion events are driven less by steady growth in volumes than by temporal clustering of vessel calls. Once such clustering occurs, congestion can escalate rapidly, even in well-equipped ports. Landside constraints further amplify these effects. When inland transport, storage, or clearance processes fail to absorb sudden surges, yards fill up, operations slow, and vessel stays lengthen further. Labor and equipment shortages during peaks can have similar effects. Under these conditions, longer vessel time in port reflects not only berth-side productivity but also system-wide coordination failures triggered by external stress.

The relationship also operates in the opposite direction. Ports are not only affected by supply chain stress but also transmit it. When vessels spend additional time in port, effective shipping capacity is reduced. Ships tied up at anchor or berth cannot be deployed elsewhere, which tightens capacity across networks and contributes to higher freight rates and lower schedule reliability. Delays incurred at one port are passed on to the next, creating cascading effects along service strings. In this way, weak port performance becomes a source of broader disruption rather than merely a local outcome.

The CPPI evidence shows that ports with higher baseline efficiency tend to damp shocks rather than amplify them. They recover more quickly, absorb less non-productive time, and experience fewer downstream delays. Conversely, ports with persistent structural inefficiencies tend to magnify stress once disruption occurs, exporting delays to trading partners and reinforcing volatility across routes. The mutual reinforcement between low CPPI scores and high supply chain stress underscores the importance of port performance for overall trade system resilience.

Data and Methodological Approach

The CPPI is based on a transparent and consistent methodological framework that has been applied across the six editions of the index. Performance is measured through observed vessel time in port, conditional on ship size and call characteristics. This approach captures the combined outcome of multiple operational and institutional factors without relying on self-reported data.

Underlying data are provided by S&P Global Market Intelligence. Data are drawn primarily from AIS-based port call records, complemented by proprietary port and terminal information. Only observed container port calls with at least one container move are included. Minimum data thresholds are applied to ensure statistical robustness and comparability.

Two complementary methods are used to construct the index. The two results are combined to produce a single CPPI score per port, with strong convergence between methods supporting robustness. Comparability over time is ensured by holding definitions, weights, and aggregation logic constant and applying them consistently to each year's data.

The CPPI provides a reliable basis for tracking performance over time and for understanding the role of ports in global supply chain dynamics. It is designed as an initial diagnostic and benchmarking instrument rather than a comprehensive performance scorecard. It should be interpreted alongside local knowledge and complementary indicators.

The annex provides the full CPPI time series for all ports across all six years, along with reference metrics for country-group comparators. It allows users to benchmark performance against global, regional, and income-group averages. The provided data helps ports to distinguish between changes driven by berth-side operations and those driven by congestion and arrival patterns.

1

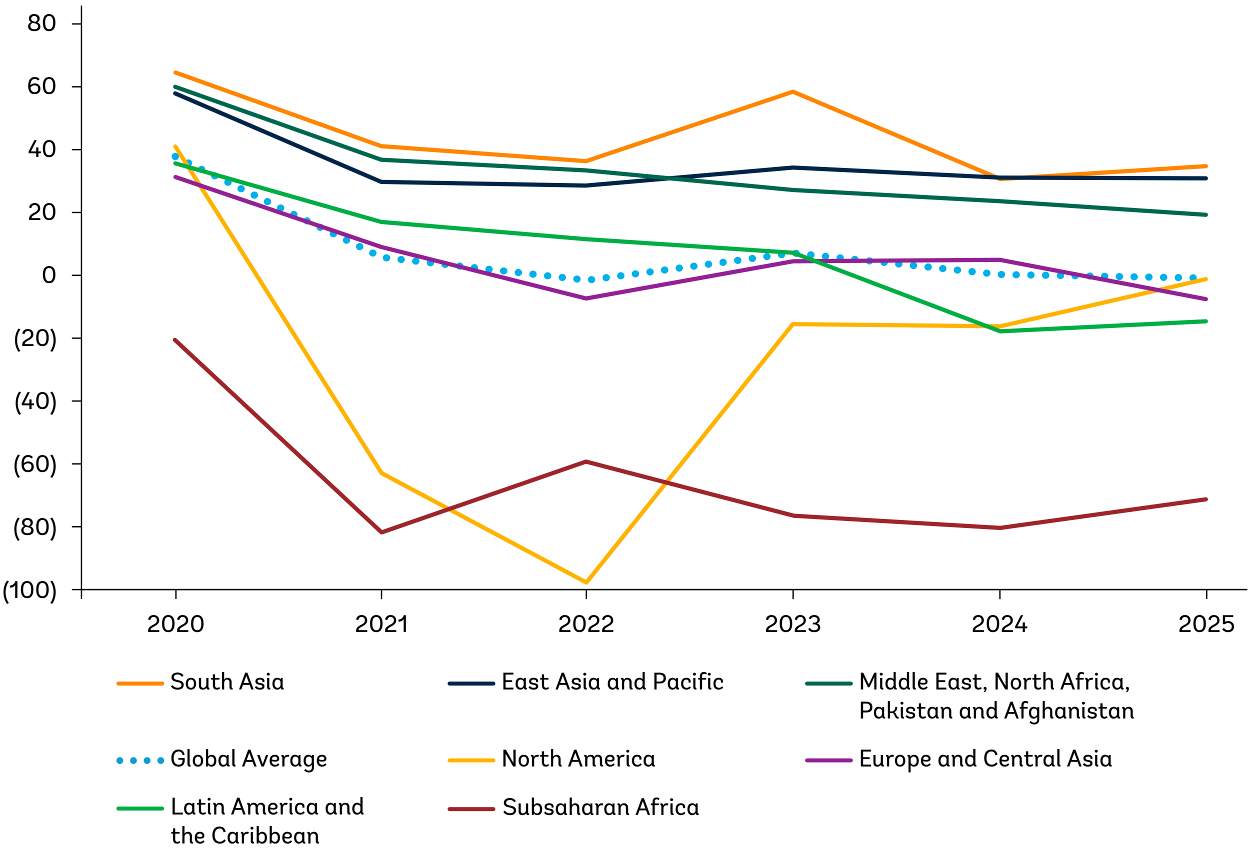
Developments in the CPPI in Different Regions and Ports

1.1 Trends in Different Regions and Income Groups

Global CPPI developments reflect diverging trends across different regions and ports. Figure 1 and Figure 2 depict the development of the CPPI across different World Bank regions and income groups.

Disaggregating CPPI results by World Bank income groups reveals a broadly positive, but nuanced, relationship between levels of development and container port performance. In 2025, upper-middle-income and high-income economies record higher average CPPI scores than lower-middle-income and low-income economies, consistent with the expectation that more developed economies are better positioned to deliver efficient port operations. At the same time, the data show that ports in upper-middle-income economies slightly outperform those in high-income economies on average, a pattern that has also been observed in several earlier years. This underlines that income level alone does not mechanically determine port performance; structure, incentives, and exposure to shocks matter.

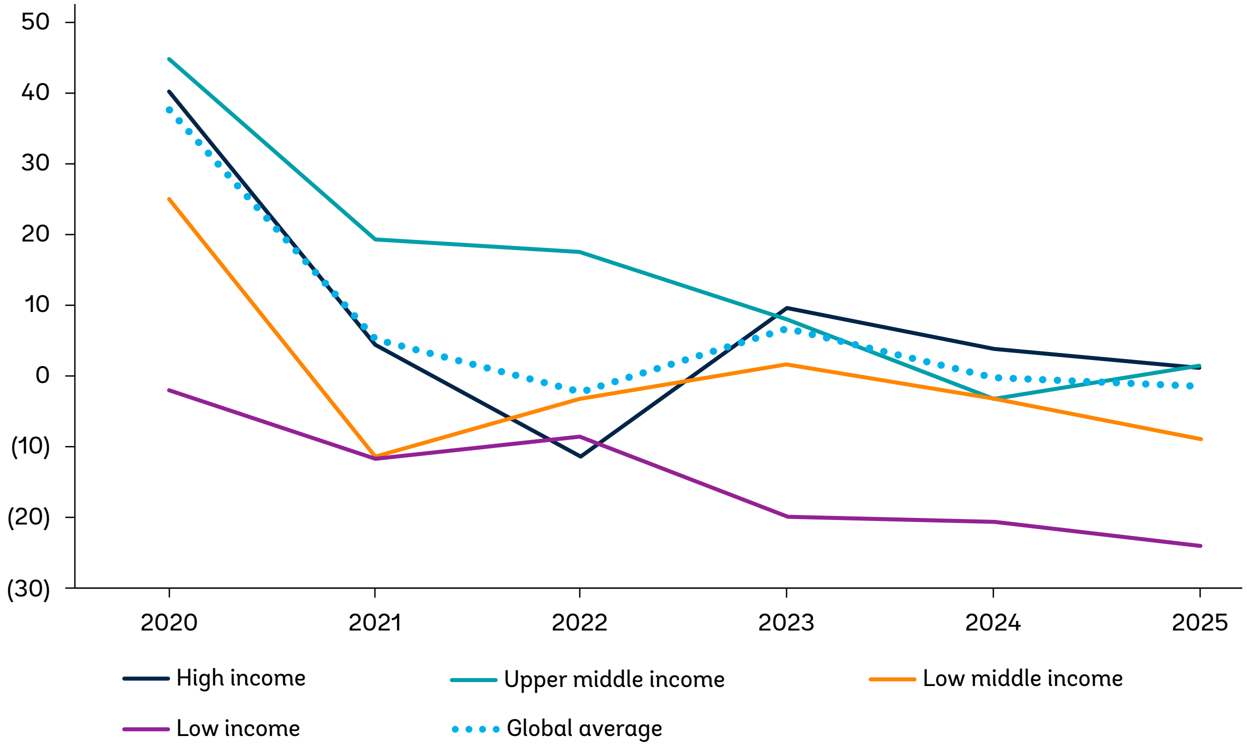
Figure 1. CPPI averages by World Bank region, 2020 to 2025



Source: World Bank calculations, based on data provided by S&P Global Market Intelligence.

Note: The global average CPPI is set at 0 in 2024. Thus, a positive CPPI score means that for a given port in a given year, vessel turn-around times (adjusted for vessel size and port call size) are shorter than the global average in 2024. A negative CPPI, accordingly, means that vessel-turn around times are slower. See Appendix 1.

Figure 2. CPPI averages by World Bank income group, 2020 to 2025



Source: World Bank calculations, based on data provided by S&P Global Market Intelligence.

Ports in higher-income economies typically benefit from lower capital costs, better port and hinterland infrastructure, including deeper channels, higher crane intensity, modern terminal layouts, and more reliable energy and ICT systems. These conditions are often complemented by wider adoption of digital tools, such as Terminal Operating Systems, Port Community Systems, and data sharing between shipping lines, terminals, and public authorities. In addition, higher-income economies tend to benefit from stronger institutional capacity, more predictable regulation, and better coordination between public and private actors, all of which support shorter vessel turnaround times and therefore higher CPPI values.

However, the CPPI time series also shows that higher income does not guarantee insulation from disruption. During the COVID-19 period, ports in Europe and North America, largely high-income regions, experienced some of the sharpest declines in CPPI, reflecting congestion driven by demand surges, labor constraints, and hinterland bottlenecks. By contrast, several ports in upper-middle-income economies, particularly in East and South Asia, rebounded faster and more strongly, benefiting from export-oriented trade structures, intense inter-port competition, and sustained investment momentum. In 2025, Europe and North America continue to recover toward pre-pandemic performance levels, but their CPPI averages remain influenced by structural congestion sensitivity and labor rigidity.

Trade structure plays a complementary role. Ports in regions that are more export-oriented than import-oriented tend to record higher CPPI scores, as export operations allow containers to be prepositioned in yards in sequence for loading, improving crane productivity and reducing idle time. Import-dominated ports, by contrast, face greater yard and storage uncertainty. This helps explain why many African ports, where import flows dominate and inter-port competition is often limited, continue to record lower average CPPI scores. In Sub-Saharan Africa, the prevalence of low-income and lower-middle-income economies, combined with constrained investment, weaker hinterland connectivity, and limited inter-port competition, results in structurally lower CPPI outcomes.

Regional trends reinforce this picture. The Middle East, which ranked among the top CPPI regions in earlier years, experienced a decline following the Red Sea crisis, reflecting widespread schedule disruption, vessel bunching, and increased arrival uncertainty. This demonstrates that even highly capital-intensive ports remain vulnerable to geopolitical shocks.

Finally, causality runs both ways. While higher income enables better port performance, improvements in port efficiency also support development by reducing trade costs, strengthening connectivity, and enhancing competitiveness. The CPPI evidence therefore points to a virtuous (but not automatic) relationship between development and port performance.

1.2 Top Performers

The twenty ports with the highest CPPI in 2025 are depicted in Table 1. A high ranking reflects above-average fast turnaround times weighted by vessel and port call categories. Most of the top-ranked ports are leading export and transshipment hubs. Table 2 presents the top 20 ports in terms of improved CPPI between 2020 and 2025. Table 3 presents the top 20 ports in terms of improved CPPI between 2023 and 2024.

Table 1. Top 20 CPPI in 2025

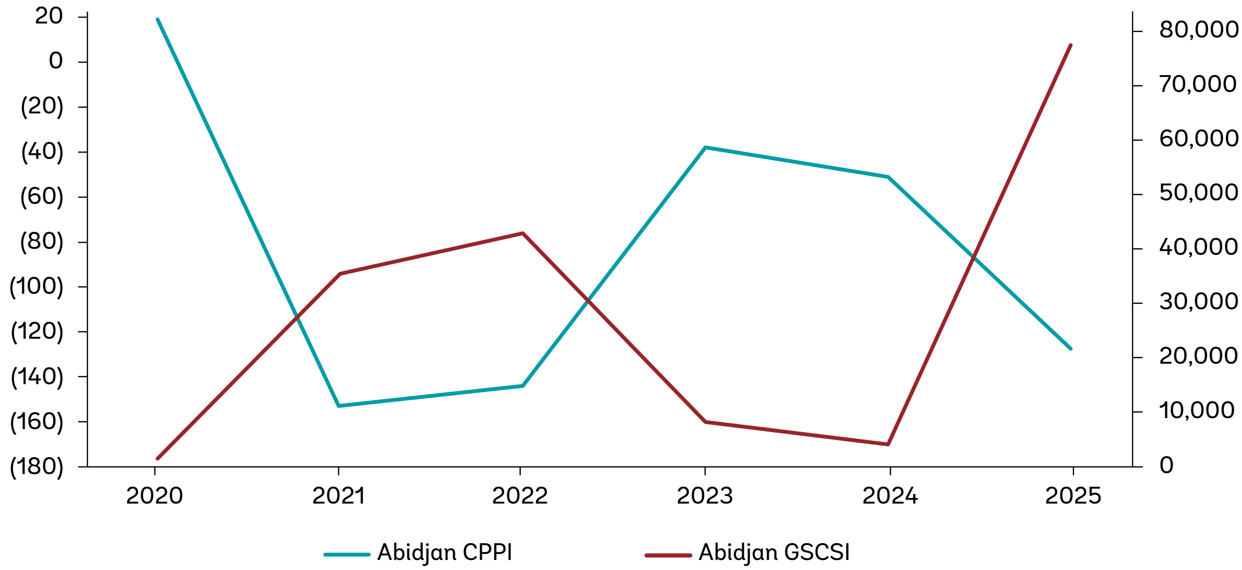
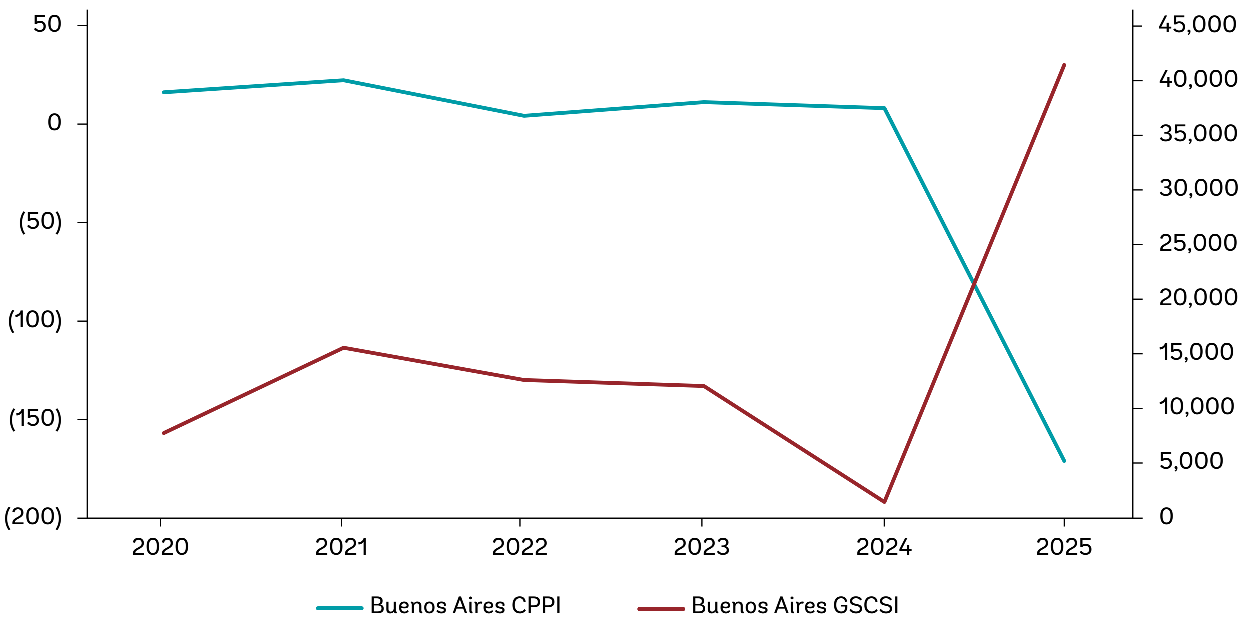
1.3 Port Performance and Supply Chain Stress for Selected Examples

Figure 3 depicts thirteen examples from different regions and situations, representing developments of the CPPI and the global supply chain stress index (GSCSI) at the port level.[1]

Figure 3. CPPI and Global Supply Chain Stress Index (GSCSI) at the port level, 2020 to 2025





[1] The Global Supply Chain Stress Index (GSCSI) is an index developed by the World Bank Group that measures global container shipping disruption based on AIS data (port calls), expressed as the volume (in TEUs) of vessel capacity delayed or stalled across ports and routes. It captures system-wide supply chain stress, including congestion and rerouting effects. See https://www.worldbank.org/en/data/interactive/2025/04/08/global-supply-chain-stress-index for the GSCSI data, and Arvis et. al. (2026) (https://www.sciencedirect.com/science/article/pii/S0966692326000293) for further background information.
The observed correlation with the GSCSI provides some validation that the CPPI also captures broader trends in maritime supply chain disruption. Correlation is expected, as the GSCSI relies on similar AIS-based measures of vessel delays, although it is constructed using a different aggregation approach based on delayed vessel capacity in TEU. This strengthens confidence in the CPPI but should not be interpreted as implying a causal relationship between the two indices.

Abidjan shows a deterioration in vessel turnaround time in 2025, largely tracking the sharp rise in congestion and supply chain stress transmitted through global liner networks. The increase in ships' time at anchor reflects irregular arrival patterns and vessel bunching following global route disruptions, notably diversions around the Cape of Good Hope. This deterioration is mirrored by a slight decline in the share of time vessels spent at berth, indicating a growing proportion of port time spent waiting rather than on productive operations. The worsening performance is consistent with external schedule unreliability.

Buenos Aires experienced a marked increase in ship time in port alongside a surge in supply chain stress, pointing to congestion effects. Global schedule disruption amplified local structural constraints, including nautical access limitations and port system fragility, resulting in longer waiting times and lower turnaround efficiency. This development coincided with a reduction in the share of time spent at berth, reinforcing the interpretation that congestion and queuing, rather than berth-side productivity alone, drove the deterioration in the CPPI. The CPPI trend thus reflects how external shocks can quickly translate into congestion in ports with limited operational slack.

Cape Town illustrates how vessel turnaround times can worsen even when broader congestion indicators fluctuate. Persistent weather-related disruption, combined with equipment reliability issues, led to high variability in ship times in port despite periods of easing supply chain stress. This deterioration was accompanied by a decline in berth utilization, suggesting that vessels increasingly accumulated time outside productive berth operations. In response, Cape Town has introduced a predictive wind model developed with the Council for Scientific and Industrial Research to reduce weather-related disruptions, a helicopter piloting service to improve ship access during high swells, and a digital technology platform for cargo planning. The port's CPPI trajectory underlines how structural exposure to external conditions can dominate performance outcomes, independent of global demand cycles.

Conakry stands out as a case where both ship turnaround time and supply chain stress deteriorated sharply in parallel. Heightened congestion followed the transmission of global schedule shocks into a port system with limited buffering capacity, leading to pronounced increases in anchorage and waiting times. This dynamic is reflected in an extreme collapse in berth utilization, with the share of time spent at berth falling from around 73 percent in 2024 to just over 37 percent in 2025. The CPPI decline primarily reflects external stress and congestion.

Dar Es Salaam benefited from the entry of private terminal operators, which reduced vessel waiting times at anchor from several weeks to a few days and improved berth allocation and operational discipline. At the same time, infrastructure upgrades under the Dar es Salaam Maritime Gateway Project, including deeper berths and channels and new cargo-handling equipment, increased handling productivity and enabled larger vessels to be served more quickly. These changes were reinforced by operational and process improvements, including fixed berthing windows and digitalization of port and customs procedures, which together reduced total vessel turnaround time from around 10–30 days to about 3–6 days.

Djibouti demonstrated a strong recovery in port turnaround times in 2025, even as regional supply chain stress remained elevated. Improved operational coordination, maturing capacity additions, and more predictable vessel arrival patterns reduced delays and stabilized turnaround times. These operational gains are reflected in a clear increase in berth utilization, with the share of time spent at berth rising from approximately 60 percent in 2024 to just over 70 percent in 2025. The port's experience highlights how effective management and learning-by-doing can offset sustained external pressure.

Durban recorded a notable improvement in vessel turnaround time in 2025, despite continued volatility in global supply chain conditions. Reduced waiting times from 20 vessels to zero compared to earlier peak-congestion years point to gradual operational stabilization and the initial impacts of equipment recovery and management reforms. This improvement coincided with a pronounced rise in berth utilization, as the share of time spent at berth increased from about 52 percent in 2024 to around 76 percent in 2025, indicating a shift away from anchorage and pre-berth delay toward productive operations. The operational gains have been supported by new investments and increased private sector participation. The most structurally significant development is the December 2025 awarding of a 25-year concession with ICTSI to modernize Durban Container Terminal Pier 2, with capacity targeted to increase from 2 million to 2.8 million TEUs from 2026. While absolute ship time in port remains long, the CPPI improvement signals recovery momentum.

Hamburg shows a mild deterioration in turnaround performance linked to renewed congestion pressures in Northern European supply chains. Periods of vessel bunching and off-schedule arrivals increased the time spent waiting and at berth, even though the port retains high structural efficiency. The CPPI trend reflects Hamburg's role as a relief node absorbing delayed arrivals.

Los Angeles has seen a clear improvement in vessel turnaround times, accompanied by a pronounced easing of congestion and supply chain stress. The normalization of arrival patterns following earlier extreme disruption reduced anchorage queues and restored fluidity across berth and yard operations. This improvement is consistent with a further rise in an already high share of time spent at berth, underscoring how congestion relief and operational discipline translate directly into shorter time ships spend in port.

Suape experienced a gradual worsening of ship turnaround time as traffic growth and ship arrivals pressed against constrained capacity. Rising yard density and nautical limitations lengthened port stays, particularly before major capacity expansion projects came on stream. This development coincided with a decline in berth utilization. The CPPI decline may thus reflect a timing mismatch between growth and infrastructure delivery rather than demand weakness.

Mombasa recorded longer vessel time in port in 2025, closely aligned with increased congestion and supply chain stress stemming from disrupted arrival patterns. Rerouting of services and higher corridor demand led to longer anchorage and pre-berth waiting times, while landside and administrative frictions amplified congestion. This deterioration was mirrored by a sharp reduction in berth utilization, reinforcing the interpretation that congestion propagated through both the maritime and hinterland interfaces. The CPPI trend captures how external shocks propagate through the port–hinterland system.

Ningbo remains a strong performer, with relatively stable and efficient ship turnaround times even as global supply chain stress fluctuated. The port's ability to sustain low time in port reflects high capacity, automation, and operational discipline, enabling it to absorb volatility without major congestion. Ningbo, therefore, exemplifies resilience at scale in a stressed global network.

Valencia provides a clear example of adaptive port performance under external stress, yet one where congestion pressures still translated into weaker measured outcomes. In line with successful efforts to accommodate additional port calls and transshipment volumes following the Red Sea crisis, vessel time outside productive operations increased. This is reflected in a decline in berth utilization, with the share of time spent at berth falling from about 64 percent in 2024 to roughly 49 percent in 2025. The simultaneous deterioration in CPPI and berth share suggests that, notwithstanding effective operational responses, sustained external pressure ultimately strained system fluidity.

Taken together, the port-level evidence reinforces the two-way relationship between supply-chain stress and time spent in port. In the majority of cases, changes in CPPI move in the same direction as changes in the share of time vessels spend at berth: improvements in CPPI are associated with a rising share of productive berth time, while deteriorations in CPPI coincide with a declining berth share.

This pattern is consistent with the notion that congestion and coordination failures in the wider supply chain both manifest themselves in, and are reinforced by, longer non-productive port time. Overall, the evidence supports a nuanced interpretation in which time spent in port is both a symptom of supply-chain stress and, when it deteriorates, a channel through which that stress feeds back into overall port and network performance. The next section will analyze this mutual relationship in more detail.

2

Vessel Time in Port and Supply Chain Stress

2.1 CPPI Trends Continue to Reflect Global Supply Chain Disruptions

In its sixth year, the CPPI time series shows that the time ships spend in ports is affected by, and affects, global and regional supply chain developments.

As already discussed in World Bank (2025a), the development of the CPPI a) closely follows and b) impacts various other indices of supply chain stress and port performance. The causality goes in both directions: a) port performance is negatively impacted by lower schedule reliability and volatile demand, but also, b) lower port performance leads to more supply chain stress on routes from and to the port.

If ships spend longer in port, this correlates with greater volatility and less schedule reliability, as well as more shipping capacity held up en route, at anchor, or at berth. The World Bank Global Supply Chain Stress Index GSCSI measures this held-up capacity. The strong correlation between the CPPI and the Global Supply Chain Stress Index is shown in Figure 4. Figure 5 depicts the CPPI alongside the global average delay for vessels arriving behind schedule, and Figure 6 depicts the percentage of vessels arriving on time.

2.2 How Supply Chain Stress Leads to Lower Port Performance

Global supply chain stress has a direct negative impact on port performance. Periods of disruption (such as pandemic-induced trade shocks or conflict-related rerouting) have empirically been associated with container vessels spending longer in port, ultimately leading to lower CPPI. This interpretation is consistent with aggregate evidence on the macroeconomic effects of global and local supply-chain disruptions (Alessandria et al. 2023).

When volatility surges and schedule reliability declines, turnaround times in ports increase. For example, 2021–22 saw record-low liner schedule reliability (just 36% on-time in 2021, down from closer to 80% pre-pandemic). As ships missed berthing windows, vessel time in port increased, and the share of the world's container fleet capacity held up in port increased accordingly. In CPPI terms, these delays translated into markedly lower scores.

When disruption causes ships to arrive together off-schedule, ports face sudden "burst congestion" events (Box 1). Rather than a steady flow, multiple delayed arrivals converge at once, rapidly overloading berths and yards. Surges in vessel arrivals erode planning and degrade schedule integrity. In such surges, even top-performing ports can be stretched beyond capacity.

Box 1. Short, sharp shocks: The rise of burst congestion in global ports

A growing share of today's port disruption is no longer explained by a steady rise in average demand. Instead, congestion increasingly arrives as short, intense episodes—'burst congestion'—that rapidly overwhelm port interfaces and then dissipate. These events are driven by the temporal clustering of vessel arrivals and workload, rather than a smooth, sustained shift in underlying volumes.

Operationally, burst congestion has a distinctive signature: periods of apparent stability are followed by sudden spikes in activity as multiple off-schedule arrivals converge within a narrow window. The resulting impacts cascade across vessels and service strings, rapidly degrading planning quality and schedule integrity.

Triggers are often a 'perfect storm' of shocks and behavioral responses. Typical triggers include severe weather, labor disruptions, geopolitical rerouting, and landside constraints. Additionally, when disruptions become widespread, they can intensify: shippers may pull forward cargo to protect service levels, raising short-term peaks and worsening yard density. This intensifies arrival clustering, turning a standard disruption into a sharper, more volatile burst.

Recent geopolitics illustrate how quickly bursts can form and migrate. In 2026, disruption in the Strait of Hormuz reduced shipping flows to a trickle, reinforcing the risk of sudden schedule dislocation and arrival compression. As carriers re-sequence networks to bypass these zones, congestion often shifts to 'relief' nodes, which can quickly become overwhelmed by the 'clumping' or synchronized arrival of diverted vessels.

Box 1. Short, sharp shocks: The rise of burst congestion in global ports (cont.)

No port, however efficient, can plan for infinite surge capacity. Traditional 'capacity buffers' designed for seasonal peaks may be insufficient for extreme bursts driven by geopolitics or synchronized schedule recovery. In these moments, 'unlocking capacity' is often less about adding physical assets and more about reducing Time Absorption—the operational friction and lag that prevents a port from returning to its baseline cadence. In an era of burst congestion, efficiency measures that minimize Time Absorption become critical because they determine whether a port can absorb a shock and recover quickly—or tip into a network-wide cascade.

Ports with higher baseline efficiency are generally better positioned to absorb and rebound from burst congestion, while those with persistent time absorption are more exposed to cascading disruptions. Ports are not powerless: resilience can be improved by reducing cycle-time volatility and strengthening recovery speed through operational discipline, better maintenance, and landside coordination. Digitization – including integrated TOS/PCS data, Predictive Berthing, and Dynamic Yard Allocation – helps ports shift from 'best-effort productivity' to a more predictable cadence. This improves recoverability when conditions deteriorate.

Alongside traditional efficiency benchmarks, periods of heightened volatility have increased interest in operational indicators that describe variability, clustering, and recovery dynamics. Where available, measures such as percentiles, threshold exceedances, and recovery-speed tracking can provide further insight into the nature and impact of burst congestion events – helping to separate persistent under-performance from short-lived overload episodes.

Shocks that cause clustering can include extreme weather, labor disruptions, and geopolitical crises. The common denominator is schedule unreliability. During 2021, for instance, the average late ship was nearly a week behind schedule, a significant delay that cascaded into port queues worldwide. With two-thirds of vessels arriving off schedule, terminals lost the ability to allocate resources efficiently, and ships were forced to wait longer at anchor and berth. In essence, volatility and lost schedule predictability directly translate into extra hours (or days) in port.

Several supply-chain shocks in recent years illustrate these dynamics. The COVID-19 pandemic initially caused wild swings in cargo flows. As consumers shifted from purchasing services (travel, restaurants, theaters, haircuts) to goods, key gateways like Los Angeles/Long Beach saw ships backing up at anchorage. Ports also faced acute labor and equipment constraints, which compounded delays. The result was unprecedented vessel turnaround times (e.g., ships waiting 1–2 weeks in queue at the peak) and a global port congestion level far above anything seen before 2020.

Another example is the Red Sea crisis of 2024–25, when Houthi attacks disrupted shipping through the Suez Canal. Many carriers rerouted vessels via the Cape of Good Hope, adding 10 to 14 days to Asia–Europe transits. This detour not only increased freight costs but also upended schedules globally. North European ports, in particular, experienced surges when delayed vessels eventually arrived together, exacerbating congestion. In such situations, ships divert around the affected zone and often "clump" at alternate ports elsewhere, overwhelming those "relief" nodes with waved arrivals. No port can instantly create infinite capacity for such rerouted flows, and the inevitable outcome tends to be longer queues and time spent in port.

Landside bottlenecks can further amplify the impact of supply chain stress on port performance. If import containers cannot be cleared due to trucking or rail constraints, terminal storage reaches capacity, and operations slow. During the COVID-19 surge, for example, inland logistics couldn't keep up in many countries, as warehouses were full and truck driver availability declined, leaving containers piling up. Such landside logjams lead carriers to impose dwell time restrictions or suspend port calls, which further worsens schedule reliability.

The impact of supply chain stress on vessel time in port is not automatic, however. Several ports that have been able to expand capacity, attracted private investment, or otherwise improved operations could reduce vessel time in ports even when they were close to regional supply chain disruptions. Even though the Red Sea crisis lead to volatility in the Indian Ocean, ports such as Djibouti and Dar Es Salaam managed to improve their CPPI score in 2025.

Still, as a general insight from analyzing six years of CPPI data, supply chain stress tends to lead to longer vessel time in ports through various mechanisms. The CPPI time series from 2020 to 2025 mirrors changes in global logistics stress and in many individual ports.

2.3 How Lower Port Performance Worsens Supply Chain Stress

Ports are not only victims of supply chain stress but also transmission points.

Congested ports can propagate delays globally: a port where vessels spend extra days creates knock-on late arrivals at the next ports of call. Thus, a vicious cycle can be formed. For example, port congestion in Asia leads to ships arriving late in Europe, which in turn causes congestion there, and so on.

Ports with higher baseline efficiency (i.e., those that minimize delays) tend to cope better with episodic shocks, whereas those with inefficiencies may suffer compounding effects. Port delays pass down the line, reinforcing why resilience in maritime supply chains and ports must go hand in hand.

Each additional hour a ship spends in port is an hour taken from the world's transport capacity, effectively shrinking the available fleet and driving up freight rates. At the height of the pandemic, container vessels spent around 20% longer in port than before, tying up ships that would otherwise be carrying cargo and contributing to an acute supply shortage at sea. Low port performance is thus not only a symptom or effect, but also a source of broader supply chain strain, potentially triggering a domino effect: the receiving port faces an off-schedule vessel that either bunches with other ships or misses critical connections, spreading congestion and schedule volatility onward.

The result is a self-perpetuating loop of stress. Delays at one node propagate to the next. Shipping lines can attempt mitigating actions, but those often carry their own costs: for example, if a vessel's turnaround is slowed at an earlier port, carriers may speed up the voyage to recover time (burning extra fuel and raising operating costs), or in some cases, skip planned port calls altogether to get back on schedule.

Such adjustments solve one problem by creating another, either by raising transport costs or leaving cargo behind. And if multiple ships are delayed at a chronically slow port, they may all arrive en masse at the subsequent hub, overwhelming it with simultaneous demand. In this way, inefficient ports essentially export their inefficiencies, transmitting stress to trade partners and trading routes worldwide.

Many ports, especially in lower-income regions, face under-investment: too few berths and cranes, shallow berths or channels that restrict ship size, and yards operating near full capacity with inadequate space. When utilization is consistently high, any unexpected surge in volume quickly translates into queueing vessels. Equipment and technology gaps further slow ship clearance. Ports in regions with lower technological, human, and institutional capacities thus generally exhibit longer vessel stays.

The pace of container handling is directly tied to crane productivity; ports that lack sufficient ship-to-shore cranes or modern yard equipment will inherently process vessels more slowly. Similarly, limited deployment of digital systems, including integrated Terminal Operating Systems or Port Community Systems, means that many ports still coordinate berthing and cargo flows in a reactive, fragmented manner. The inability to share real-time data between shipping lines, terminals, truckers, and depots leads to planning failures: trucks and containers don't arrive when needed, berths lie idle awaiting resources, and precious time is lost.

In essence, weak port performance acts as an accelerant of supply chain stress. By consuming extra time and capacity, an inefficient port creates ripple effects: ships arrive late downstream, carriers and shippers incur higher costs, and the entire system faces greater volatility in schedules and deliveries. This mutual relationship means that strengthening port performance is not only a local efficiency goal but a key component of bolstering global supply chain resilience. By minimizing the time ships spend in port and avoiding delays, ports can cease being stress transmitters and instead become stabilizers in an increasingly unpredictable global trade environment.

Annex

Annex 1: Methodology and Use of the CPPI for Tracking Performance Over Time

The methodology applied in the 2025 Container Port Performance Index (CPPI) is unchanged from that used in the 2025 report, which covered the CPPI from 2020 to 2024. Rather than repeating the full technical description already documented in detail in the five preceding CPPI reports, this annex summarizes the core principles of the methodology, highlights aspects most relevant for interpreting trends over time, and explains how supporting information provided in the Annex can be used by ports and stakeholders for benchmarking and self-assessment.

Detailed, step-by-step explanations of the data structure, variable definitions, imputation procedures, and index construction methods can be found on the World Bank CPPI web page. Bartholomew et al. (2011) and Lee and Seung (1999) provide the theoretical foundation for the used approach, while Ashley et al. (2023) explain how this approach is specifically applied to generate the CPPI.

Conceptual foundation: measuring vessel time in port

The CPPI is based on a simple and transparent principle: container port performance is measured through the time container ships spend in port, conditional on ship size and call size. Time in port reflects the combined outcome of a wide range of operational, organizational, nautical, and institutional factors, including berth productivity, terminal coordination, arrival sequencing, waiting time at anchor, and port-hinterland interfaces.

Using vessel time in port as the core performance metric offers three key advantages. First, it relies on empirical, observed behavior rather than self-reported indicators. Second, it captures the experience of shipping lines directly, reflecting how ports perform within real operating networks. Third, it provides a common denominator that allows comparison across ports of different sizes, regions, and development levels, as well as over time.

Time in port is decomposed into three standardized subcomponents:

- Arrival time: time at anchor or in waiting areas, plus time moving toward the berth
- Berth time: the period between all-lines-fast and all-lines-released, including cargo operations
- Departure time

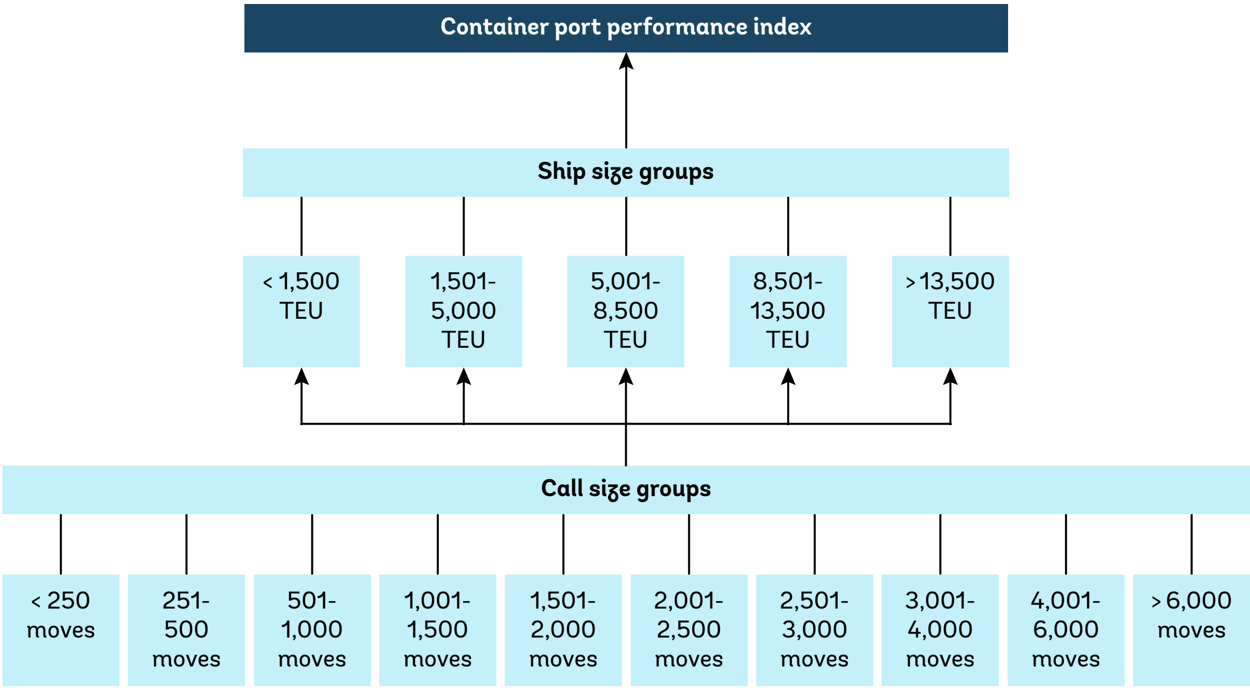
The CPPI is calculated from arrival and berth times. These definitions are unchanged from previous CPPI editions and are summarized in the glossary.

Data source and coverage

The CPPI is built on port call–level data provided by S&P Global Market Intelligence via its Port Performance Program, primarily drawn from Automatic Identification System (AIS) records and proprietary port and terminal information. Only observed port calls with at least one container move are included. For all ports, the same minimum data thresholds are applied to ensure statistical robustness. Ports with insufficient observations are excluded from index computation but remain visible in the underlying datasets.

Figure 7 depicts the structure of the CPPI. Port calls are grouped into five standardized ship size categories: feeders (<1,500 twenty-foot equivalent units, TEUs), intra-regional (1,501 TEUs–5,000 TEUs), intermediate (5,001 TEUs–8,500 TEUs), neo-panamax (8,501 TEUs–13,500 TEUs), and ultra-large container carriers (>13,500 TEUs). The five ship-size groups were based on where ships might be deployed and on the similarities among ships within each group. For each category, there are ten different bands for call size. The 10 call size groups were selected to ensure a similar level of crane intensity across groups.

Figure 7. Structure of the CPPI



Source: World Bank

A key feature of the CPPI methodology is that all performance indicators are constructed separately for different ship size groups, recognizing that operational dynamics differ substantially between feeder vessels and ultra large container ships. Port level results are then consistently aggregated across ship sizes.

Construction of the CPPI: two complementary approaches

The CPPI continues to rely on two complementary methodological approaches, summarized here without repeating their full technical specifications.

The **administrative approach** uses a structured, transparent aggregation of normalized vessel time-in-port indicators across ship and call-size groups. Performance is assessed relative to global averages, with ports receiving positive or negative contributions depending on whether they perform better or worse than the benchmark within each category. This approach reflects expert knowledge of port operations and ensures intuitive interpretability.

The **statistical approach** looks at all the available time-in-port information for each port together, rather than one measure at a time, to understand how ports perform overall. It identifies some of the main patterns that run through the data. In doing so, it gives more weight to information that consistently points in the same direction and less weight to isolated or inconsistent observations. This helps to avoid over-emphasizing any single indicator. By combining the different pieces of information into a smaller number of clear signals, the statistical approach makes the results easier to compare across ports. It also ensures that the final scores are balanced and consistent, because it takes into account that many of the underlying indicators are related to each other.

As in recent CPPI editions, the two resulting scores are combined to produce a single CPPI score per port, the average of the "administrative" and "statistical" scores. The high degree of convergence observed between the two approaches in recent years supports the index's robustness and reduces its sensitivity to methodological assumptions.

Ensuring comparability over time

A central objective of the CPPI since last year's report has been to enable tracking of port performance over time. This is achieved not by recalibrating the index average each year, but by holding the methodology, definitions, and aggregation logic constant and applying them consistently to new annual data.

Annex 2 includes all six CPPI editions (2020–2025) in a harmonized structure, allowing users to observe how individual ports' performance evolves across years. Year on year changes in CPPI scores therefore reflect genuine changes in observed vessel time in port, rather than methodological recalibration.

Use of data for benchmarking and comparison

Annex 2, provided in Excel (XLSX) format, is integral to the CPPI methodology and its usability. It is deliberately designed to allow users to go beyond headline rankings. It includes the CPPI score for all 6 years to observe trends over time. In addition, for 2025, it includes

- The port's UN/LOCODE
- The percentage of vessel time spent at berth
- Aggregated averages for World Bank income groups, World Bank regions, and maritime regions
- The sample size, i.e., the number of port calls for which data were available to generate the 2025 CPPI score

By including these reference averages, the downloadable data enables ports to assess their performance not only against the global mean, but also relative to peer groups that reflect similar economic or geographic contexts. Users can create custom comparison groups, for example, by combining regions, income levels, port size categories, or other characteristics relevant to their operational reality.

The berth-time percentage column can be of interest for diagnostic purposes, as it allows ports to distinguish between changes driven by berth-side operations and those driven by arrival patterns, anchorage delays, or pre-berth congestion.

A new feature introduced in this year's report (Annex 2) is the inclusion of the sample size, indicating the number of port calls available to S&P Global Market Intelligence for each port and year.

Interpretation, limitations, and additional data sources

The CPPI is designed as a diagnostic and benchmarking tool, not as a comprehensive measure of port performance or a scorecard of management quality. It reflects outcomes—measured through vessel time in port—rather than inputs or institutional arrangements. Ports should therefore interpret CPPI results in conjunction with local knowledge and complementary indicators. At the same time, the consistent application of the methodology over six years makes the CPPI useful for identifying potential performance gaps, structural improvements, and shifts in exposure to external shocks.

The CPPI is based on the time ships spend in port. For a comprehensive assessment of a port's performance, additional data available at the port level should be taken into account.

- The World Bank Global Supply Chain Stress Index (GSCSI) is available for nearly 400 ports every quarter.[2]
- The World Bank Logistics Performance Indicators (LPI) are available on the country level, covering, among other indicators, cargo dwell time in ports.[3]
- The UNCTAD MDST Liner Shipping Connectivity Index (LSCI) is available for over 800 ports, providing an indicator for a port's position in the global liner shipping network.[4]

The CPPI and these complementary global indicators together provide neutral indicators to port stakeholders that allow them to observe trends over time and see how their ports compare to other ports under the specific, clearly defined benchmarks.

Source: World Bank, based on data provided by S&P Global Market Intelligence.
For further details and deeper insights into the Container Port Performance Index, readers can explore the underlying data that informs it. By accessing S&P Global's Port Performance dataset, readers can benchmark global container port and terminal performance. For more information about the underlying data and our Port Performance Program, see https://www.spglobal.com/market-intelligence/en/solutions/products/port-performance.

Notes:

[a] World Bank Region: EAP = East Asia and Pacific, ECA = Europe and Central Asia, LAC = Latin America and the Caribbean, MENAAP = Middle East, North Africa, Afghanistan and Pakistan, NAM = North America, SAR = South Asia Region, SSA = Sub-Saharan Africa.

[b] World Bank Income Groups: HI = High Income, LI = Low-Income, LMI = Lower Middle-Income, UMI = Upper Middle Income.

[c] The share of time at berth in per cent of total time in port used for CPPI calculation. Total time in port does not include the vessel's departure time.

* Yangshan has been incorporated into Shanghai port for CPPI 2025.

** Venezuela, RB, classified as an upper-middle-income country until FY21, has been unclassified since then due to data unavailability.
